

Redundancy of Application Server

Redundancy of application server

For such an application, the D2000 system consists of two or several application servers (processes [D2000 Server](#)).

The following figure shows D2000 system with two application servers (A and B):

Redundant system comprises one or several application servers. The servers form so called **Redundant group (RDG)**. Each of the application servers can be in different states. In ordinary circumstances (during the standard operation), there is just one server in the state **HOT Server (HS)** and the others are in the state **STANDBY Server (SBS)**. HS is active and as the only one performs all tasks resulting from its configuration. All SBS servers check the presence of the HS and they are connected to the HS as client processes. Process name is the same as server name with the suffix **KNL** in the RDG. The HS keeps all SBS servers informed about changes in the configuration and the current values of all objects included in the configuration. Therefore, each of the SBS servers is capable of taking over the HS function at any moment.

For such a configuration of redundant system, there are several methods for connecting clients to application server.

1. **Direct connection to application server** - process is started without parameters, if is placed on the same computer as the server, or using the parameter **/S** from a remote computer. When the process is connected successfully, it is informed about the current state of the server. If the server is HS, the process activity is not limited in any way and the process keeps its functionality according to the process type. If the server is SBS, the process activity is limited by its type (see the chapter [Activity of processes within RDG](#)).
2. **RDS connection** - process is started with the parameter **/RD** (or **/RF**) along with the RDG name. The information is used by the process, when looking for the HS of the given RDG. After making a connection, the process begins to operate.

Some other properties of RDG :

- In every moment, there is active just one Server, so-called Hot Server (**HS**). The other members of **RDG** are in the state **SBS**.
- All computers with running **RDG** members must be available to each other by means of **MULTICAST** messages.
- After unexpected termination of HS or after starting the Server, the RDS members elect a new **HS**. New HS is selected and the other servers in the state SBS will be automatically restarted.
- During operation, the configuration database of every **RDG** member is kept synchronized with the **HS** configuration.
- After starting a new **RDG** member, before changing into the state **SBS**, its configuration database is automatically fully synchronized with the configuration database of the current **HS**.
- Server started as a **RDG** member, keeps testing its connection to the network and visibility of defined computers using the service PING. If none of the computers responds, the server will be automatically stopped.
- Server status can be changed into the state **HS** if its priority is greater than 0 and the parameter *State* in the list of **RDG** parameters is set to SBS.
- Request to switch the server to the state **HS** if the server is in other state than **SBS**, will terminate it.
